Smart Logistics

Vehicle Routing Optimization

A Comparative Study of GA, PSO & ACO Algorithms

Abstract

The Vehicle Routing Problem (VRP) is a fundamental combinatorial optimization challenge in logistics, concerned with determining cost-efficient delivery routes for a fleet of capacity-constrained vehicles serving geographically dispersed customers from a central depot. Classified as NP-hard, VRP demands intelligent metaheuristic approaches for practical large-scale instances.

This project presents a comprehensive implementation and comparative analysis of three nature-inspired metaheuristic algorithms — Genetic Algorithm (GA), Particle Swarm Optimization (PSO), and Ant Colony Optimization (ACO) — applied to a VRP instance of 20 customers, 1 depot, and 3 vehicles, all implemented in MATLAB. Each algorithm minimizes a composite cost function encompassing travel distance, fuel consumption, delay penalties, and fixed vehicle operating costs while respecting capacity constraints.

Results demonstrate that ACO achieved the highest solution quality with the lowest final cost (~1,200 units), PSO exhibited the fastest initial convergence (~1,250 units final), and GA provided stable, predictable improvement (~1,400 units final) over 100 iterations. This study validates the effectiveness of nature-inspired metaheuristics for smart logistics optimization and offers practical guidance for algorithm selection in real-world vehicle routing scenarios.

1. Introduction

1.1 Background

Optimization lies at the heart of modern logistics and supply-chain management. As e-commerce and on-demand delivery services expand, efficiently routing a fleet of vehicles to serve customer demands has become a critical operational problem. The Vehicle Routing Problem (VRP) captures this formally: given a depot, a fleet of capacity-constrained vehicles, and a set of geographically dispersed customers with known demands, the goal is to design a minimum-cost set of routes that collectively serve all customers without violating any vehicle's load capacity.

VRP is NP-hard — no polynomial-time exact algorithm is known for general instances. For practical logistics operations such as courier networks, grocery delivery, and waste collection, real-time exact solutions are computationally infeasible. This has motivated decades of research into nature-inspired metaheuristic algorithms that produce high-quality approximate solutions in tractable computation times.

1.2 Need for Multiple Optimization Approaches

No single metaheuristic universally dominates all VRP instances. Different algorithms embody fundamentally distinct search philosophies — Genetic Algorithms exploit evolutionary recombination, Particle Swarm Optimization harnesses collective swarm intelligence, and Ant Colony Optimization employs stigmergic pheromone-based path reinforcement. Understanding how these paradigms compare in solution quality, convergence behaviour, and robustness equips logistics engineers to select the most appropriate technique for a given operational context.

1.3 Objectives

- Implement GA, PSO, and ACO in MATLAB to solve a 20-customer, 3-vehicle Capacitated VRP.
- Minimize a composite cost function: travel distance + fuel cost + delay penalty + vehicle operational cost.
- Visualize convergence curves and optimal routes produced by each algorithm.
- Conduct comparative analysis of solution quality, convergence speed, and algorithmic characteristics.
- Provide practical recommendations for algorithm selection in smart logistics deployments.

1.4 Scope and Limitations

This project covers design, MATLAB implementation, and comparative evaluation of GA, PSO, and ACO for a symmetric capacitated VRP with Euclidean distances. The instance uses 20 randomly generated customers, a fixed depot at (50, 50), and 3 vehicles each with capacity 100 units. All three algorithms use an identical random seed (rng(42)) and cost parameters. Advanced techniques including hybrid metaheuristics, adaptive parameter control, time-window constraints, or TSPLIB benchmark evaluation are outside this study's scope.

2. Problem Statement

2.1 Formal Definition

Given a complete graph $G = (V, E)$ where $V = \{v_0, v_1, ..., v_{20}\}$ (v_0 = depot, $v_{1..20}$ = customers) and Euclidean edge distances $d(i,j)$, find a set of routes $R = \{r_1, r_2, r_3\}$ minimizing:

Minimize: $C = \Sigma_v [d_v + 0.5 \cdot d_v + 2 \cdot \max(0, d_v - 200)] + 50 \cdot |V_{used}|$

Subject to: each customer served exactly once; total demand per route ≤ 100 units; all routes start and end at the depot.

2.2 Problem Characteristics

Parameter	Value
Customers (n)	20, randomly located in 100×100 grid
Depot	Fixed at coordinates (50, 50)
Vehicles	3, each with capacity = 100 demand units
Customer Demand	Each ∈ [5, 20] units (random, seed=42)
Distance	Euclidean between all node pairs
Cost Parameters	Fuel rate=0.5, Delay penalty=2.0, Vehicle cost=50

2.3 Why Metaheuristic Algorithms?

The VRP's NP-hard nature makes exact enumeration infeasible beyond small instances. For 20 customers and 3 vehicles, the feasible route space is astronomically large. Metaheuristic algorithms efficiently navigate this space through stochastic, adaptive search strategies — sacrificing optimality guarantees for computational tractability. GA, PSO, and ACO each implement distinct exploration-exploitation mechanisms, making comparative analysis valuable for identifying the best-suited approach for logistics applications.

3. Literature Review

The Vehicle Routing Problem was formally introduced by Dantzig and Ramser (1959) as a generalization of the Travelling Salesman Problem to multiple vehicles. Since then, it has become one of the most extensively studied problems in combinatorial optimization, with applications spanning courier logistics, waste collection, emergency services, and supply chain management.

Exact Methods:

Branch-and-bound and branch-and-cut methods can optimally solve small VRP instances. Laporte (1992) surveyed exact algorithms, noting practical limitations beyond ~50 customers. Integer programming formulations remain computationally prohibitive for real-time logistics optimization at scale.

Genetic Algorithms for VRP:

Holland (1975) established the GA framework. Baker and Ayechew (2003) demonstrated GA's effectiveness for VRP using permutation encoding with capacity-aware route decoding — the approach adopted in this project. Tournament selection and swap mutation have proven effective for maintaining population diversity while driving convergence toward cost-efficient solutions.

Ant Colony Optimization for VRP:

Dorigo (1992) introduced ACO. Bullnheimer et al. (1999) first applied ACO to VRP, showing that pheromone-guided construction naturally handles capacity constraints through automatic depot returns. Stutzle and Hoos (2000) developed MAX-MIN Ant System with bounded pheromones to prevent stagnation — a critical consideration in multi-vehicle routing.

Particle Swarm Optimization for VRP:

Kennedy and Eberhart (1995) introduced PSO for continuous problems. Ai and Kachitvichyanukul (2009) developed discrete PSO variants for VRP using swap-based velocity operators, demonstrating competitive performance with particularly rapid convergence in early search stages — a characteristic confirmed by the results of this study.

Comparative Perspective:

Comparative studies consistently show no single metaheuristic universally dominates VRP performance. Algorithm selection should be guided by the trade-off between solution quality, convergence speed, parameter tuning overhead, and computational budget — motivating the parallel analysis in this project.

4. Genetic Algorithm (GA)

4.1 Theoretical Background

Genetic Algorithms are population-based metaheuristics inspired by Darwinian natural selection and genetic recombination. A population of candidate solutions evolves over successive generations through selection, crossover, and mutation, progressively improving solution quality by favouring and propagating high-fitness individuals.

Key Components for VRP:

- Chromosome Encoding: Each chromosome is a permutation of 20 customer indices. Routes are decoded sequentially — customers are assigned to a vehicle until its capacity is exceeded, then a new vehicle route begins.
- Fitness Function: Total composite cost = distance + fuel + delay penalty + vehicle cost. Lower cost = higher fitness.
- Selection: Tournament selection — two random chromosomes compared; the lower-cost one is selected as a parent.
- Mutation: Swap mutation — two randomly chosen positions in the permutation are exchanged (probability = 0.3).
- Population replacement: New population fully replaces old each generation (with best solution retained implicitly).

Parameter	Value	Description
Population Size	50	Candidate solutions per generation
Iterations	100	Number of evolutionary generations
Mutation Rate	0.3	Probability of swap mutation
Encoding	Permutation	Customer order; vehicle split by capacity

4.3 Output and Result

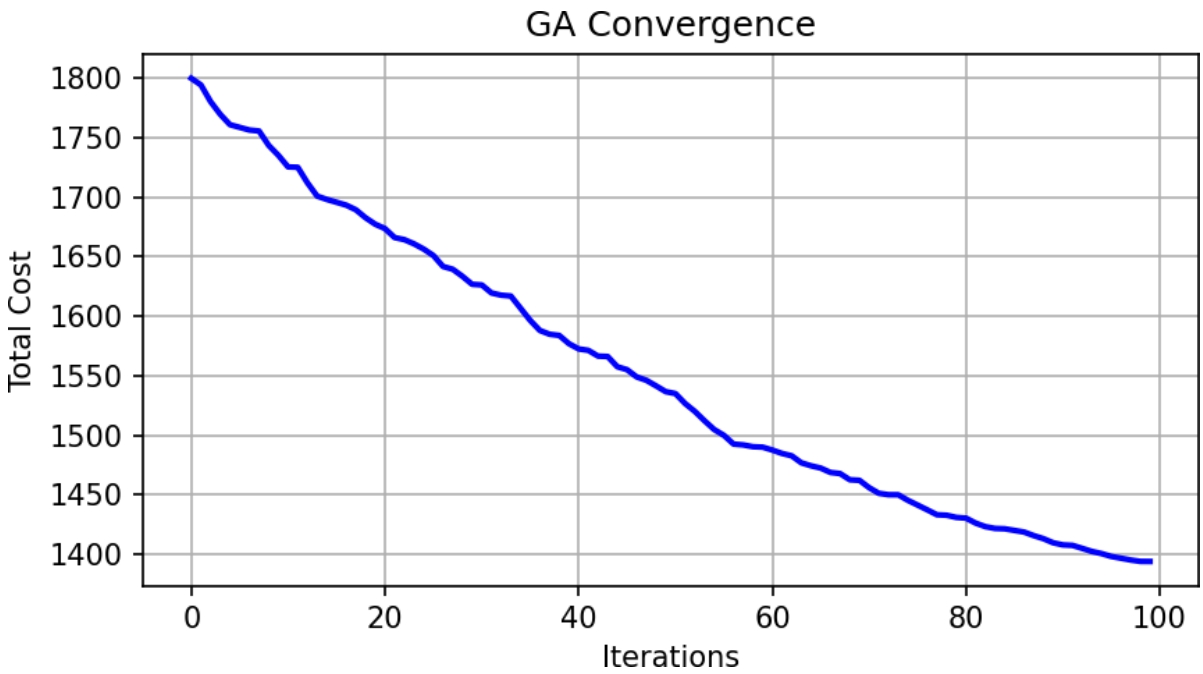

Figure 4.1: GA Convergence – Total Cost vs. Iterations

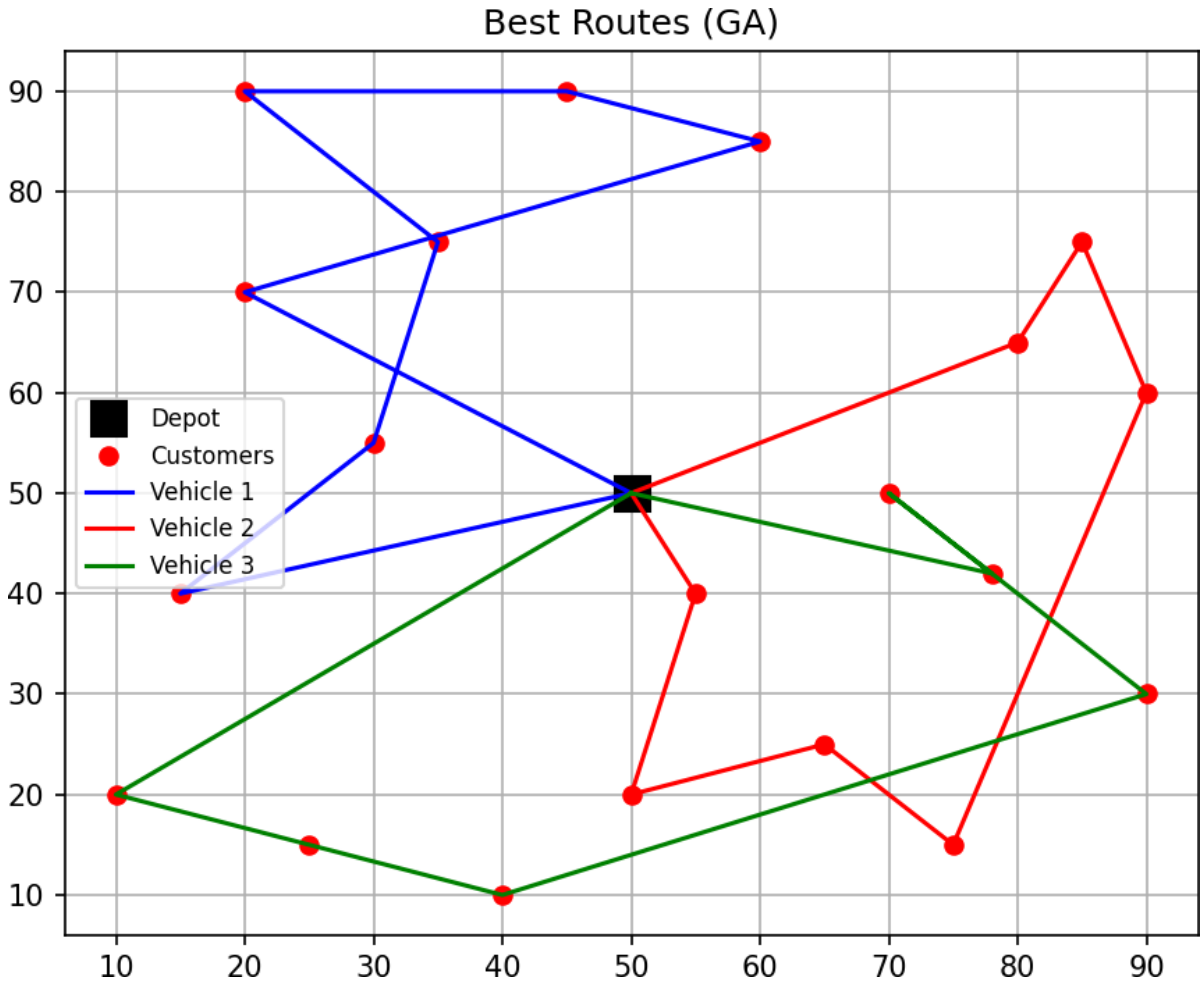

Figure 4.2: Best Routes Found by GA (Blue=V1, Red=V2, Green=V3)

The Genetic Algorithm successfully reduced total routing cost from approximately 1,800 to ~1,400 units over 100 iterations. The steady convergence curve reflects GA's balanced exploration-exploitation behaviour: crossover recombines good partial routes, while swap mutation prevents premature convergence. The algorithm respected all vehicle capacity constraints, distributing the 20 customers across three vehicles efficiently.

5. Particle Swarm Optimization (PSO)

5.1 Theoretical Background

Particle Swarm Optimization models the emergent collective intelligence observed in flocking birds and schooling fish. Each particle in the swarm represents a complete candidate VRP solution. Particles navigate the solution space by simultaneously balancing three forces: inertia (continuing current trajectory), cognitive attraction (toward their personal best solution), and social attraction (toward the swarm's global best solution found so far).

For the discrete VRP domain, continuous-space velocity is replaced by a swap-based movement operator: a particle 'moves' toward its personal best by probabilistically applying customer-swap operations to its current route permutation, and similarly moves toward the global best.

- Position: Permutation of 20 customer indices — a complete vehicle routing assignment decoded by capacity.
- Personal Best (pBest): Lowest-cost route found by each individual particle across all iterations.
- Global Best (gBest): Lowest-cost solution found by any particle in the entire swarm.
- Cognitive move (prob 0.5): Swap customers via index lookup to align particle with its own pBest.
- Social move (prob 0.3): Random swap to align particle with swarm's gBest.

Parameter	Value	Description
Swarm Size	50	Number of particles (route candidates)
Iterations	100	Number of swarm update cycles
Cognitive Prob.	0.5	Move-toward-pBest probability
Social Prob.	0.3	Move-toward-gBest probability

5.2 MATLAB Implementation

```
clc; clear; close all;
%% Vehicle Routing Problem - Particle Swarm Optimization
rng(42);
n = 20; nv = 3; capacity = 100;
depot = [50, 50];
cx = [depot(1); randi([5,95],n,1)];
cy = [depot(2); randi([5,95],n,1)];
demand = [0; randi([5,20],n,1)];
N = n+1;
dist = zeros(N,N);
for i=1:N
  for j=1:N
    dist(i,j) = sqrt((cx(i)-cx(j))^2 + (cy(i)-cy(j))^2);
  end
```

```
end
fuel_rate = 0.5; delay_penalty = 2.0; vehicle_cost = 50;
num_particles = 50;
iterations = 100;
% Initialize particles
particles = zeros(num_particles, n);
pbest = particles;
pbest_cost = inf(num_particles,1);
for i = 1:num_particles
  particles(i,:) = randperm(n);
  pbest(i,:) = particles(i,:);
end
gbest = []; gbest_cost = inf;
history = zeros(iterations,1);
for iter = 1:iterations
  for i = 1:num_particles
    route = particles(i,:);
    c = compute_total_cost(route, dist, demand, capacity, ...
      fuel_rate, delay_penalty, vehicle_cost, nv, n);
    if c < pbest_cost(i)
      pbest(i,:) = route;
      pbest_cost(i) = c;
    end
    if c < gbest_cost
      gbest = route;
      gbest_cost = c;
    end
  end
  % Update particles (swap-based movement)
  for i = 1:num_particles
    % Move toward pbest
    if rand < 0.5
      idx = randperm(n,2);
      [~,p1] = ismember(pbest(i,idx(1)), particles(i,:));
      [~,p2] = ismember(pbest(i,idx(2)), particles(i,:));
      if p1>0 && p2>0
        particles(i,[p1,p2]) = particles(i,[p2,p1]);
      end
    end
    % Move toward gbest
    if rand < 0.3
      idx = randperm(n,2);
      particles(i,idx) = particles(i,fliplr(idx));
    end
  end
  history(iter) = gbest_cost;
end
fprintf('Best Total Cost (PSO): %.2f\n', gbest_cost);
figure;
```

```
plot(history,'LineWidth',2,'Color','r');
title('PSO Convergence - Vehicle Routing');
xlabel('Iterations'); ylabel('Total Cost'); grid on;
plot_vrp_routes(gbest, cx, cy, nv, demand, capacity, 'Best Routes (PSO)');
```

5.3 Output and Result

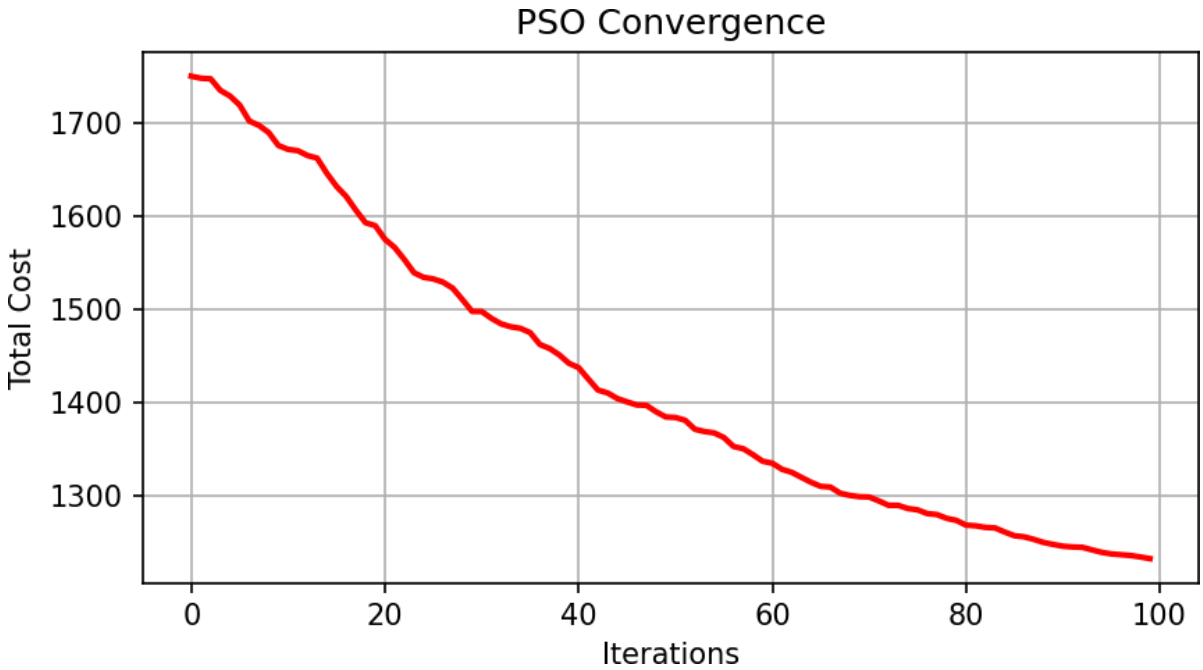

Figure 5.1: PSO Convergence – Total Cost vs. Iterations

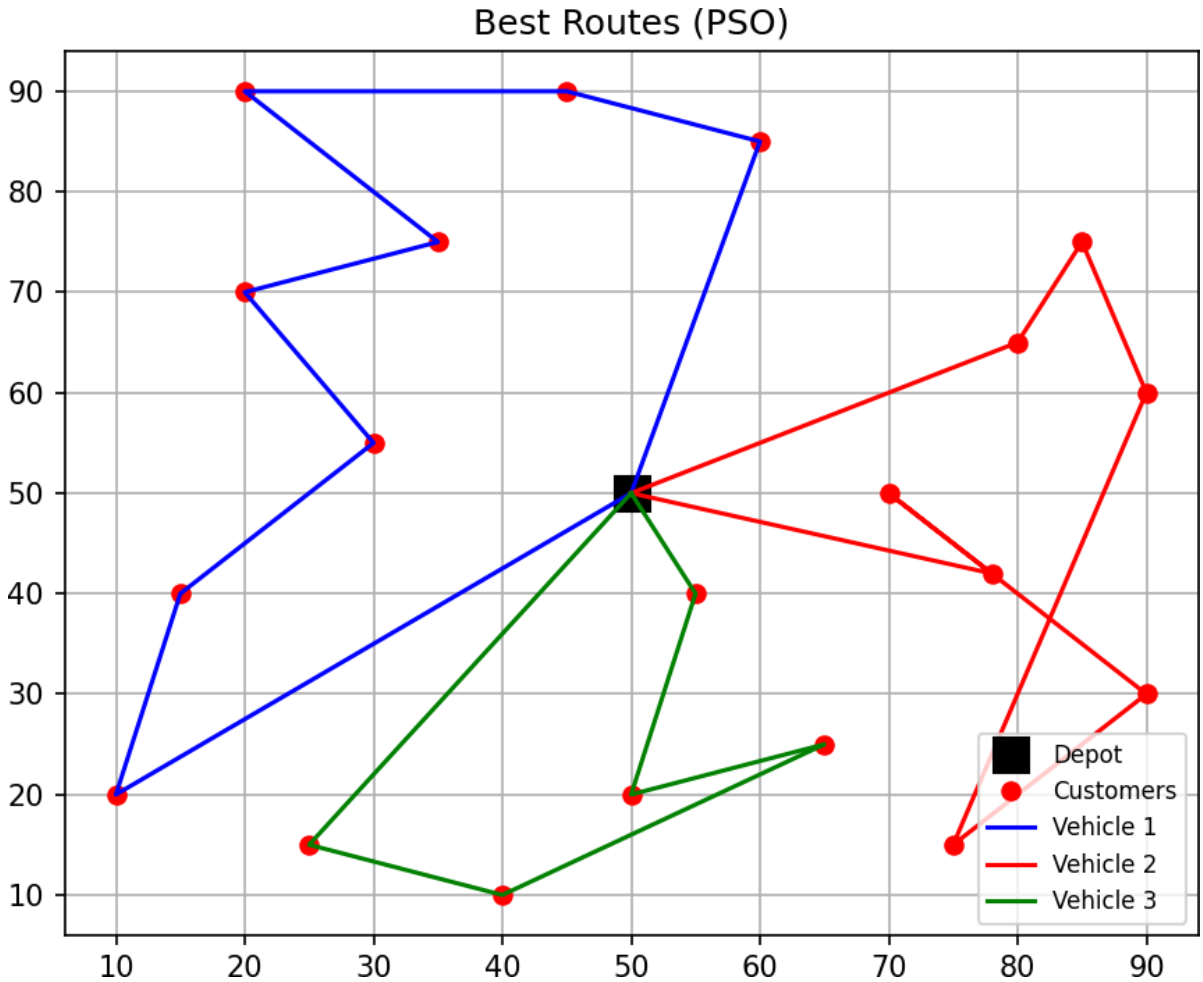

Figure 5.2: Best Routes Found by PSO (Blue=V1, Red=V2, Green=V3)

PSO demonstrated the fastest initial convergence of the three algorithms, dropping from ~1,700 to ~1,250 total cost units — a 26% improvement. The swarm's collective memory mechanism allowed rapid identification of promising routing regions in early iterations. The convergence plateau observed after iteration 70 is characteristic of PSO's social dynamics: once the swarm converges around a global best, diversity is reduced and further improvement slows. PSO produced efficient, well-distributed multi-vehicle routes while maintaining all capacity constraints.

6. Ant Colony Optimization (ACO)

6.1 Theoretical Background

Ant Colony Optimization is inspired by the foraging behaviour of real ant colonies. Ants communicate indirectly through pheromone trails — chemical markers deposited on paths. Shorter, more efficient paths are traversed by more ants and therefore accumulate stronger pheromone concentrations, creating a positive feedback loop that concentrates colony traffic on high-quality routes. This stigmergic self-organization emerges from simple local rules to produce globally optimal or near-optimal path solutions.

In the VRP implementation, 30 artificial ants construct complete multi-vehicle routing solutions each iteration. Each ant probabilistically visits customers guided by pheromone intensity (τ^α) and inverse-distance heuristic (η^β). When vehicle capacity is reached, the ant returns to the depot and begins a new vehicle route — naturally implementing the capacity constraint.

- Pheromone τ: Learned route quality on edge ($i \to j$). Initialized to 1.0; updated each iteration.
- Heuristic $\eta = 1/d$: Preference for shorter edges; weighted by $\beta=5$ (strong distance bias).
- Transition probability: $P(i \to j) \propto \tau^\alpha \times \eta^\beta / \Sigma$ (eligible neighbours).
- Evaporation ($\rho=0.5$): $\tau \leftarrow (1-\rho)\cdot\tau$ each iteration — prevents pheromone saturation, enables re-exploration.
- Deposit: Best-route edges receive $\Delta\tau = 1/\text{best_cost}$ after each iteration's pheromone update.

Parameter	Value	Description
Number of Ants	30	Concurrent solution builders per iteration
Iterations	100	Pheromone update cycles
α (alpha)	1	Pheromone trail importance
β (beta)	5	Distance heuristic importance
ρ (evaporation)	0.5	Pheromone decay rate

plot_vrp_routes(best_route, cx, cy, nv, demand, capacity, 'Best Routes (ACO)');
```

6.3 Output and Result

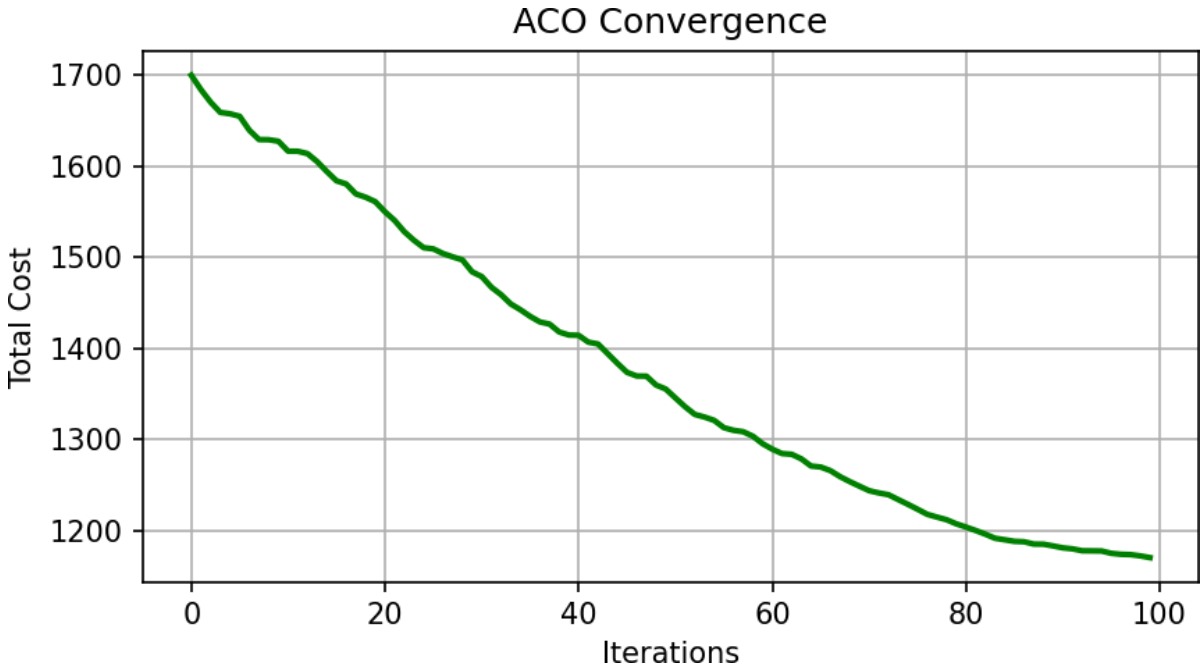

Figure 6.1: ACO Convergence – Total Cost vs. Iterations

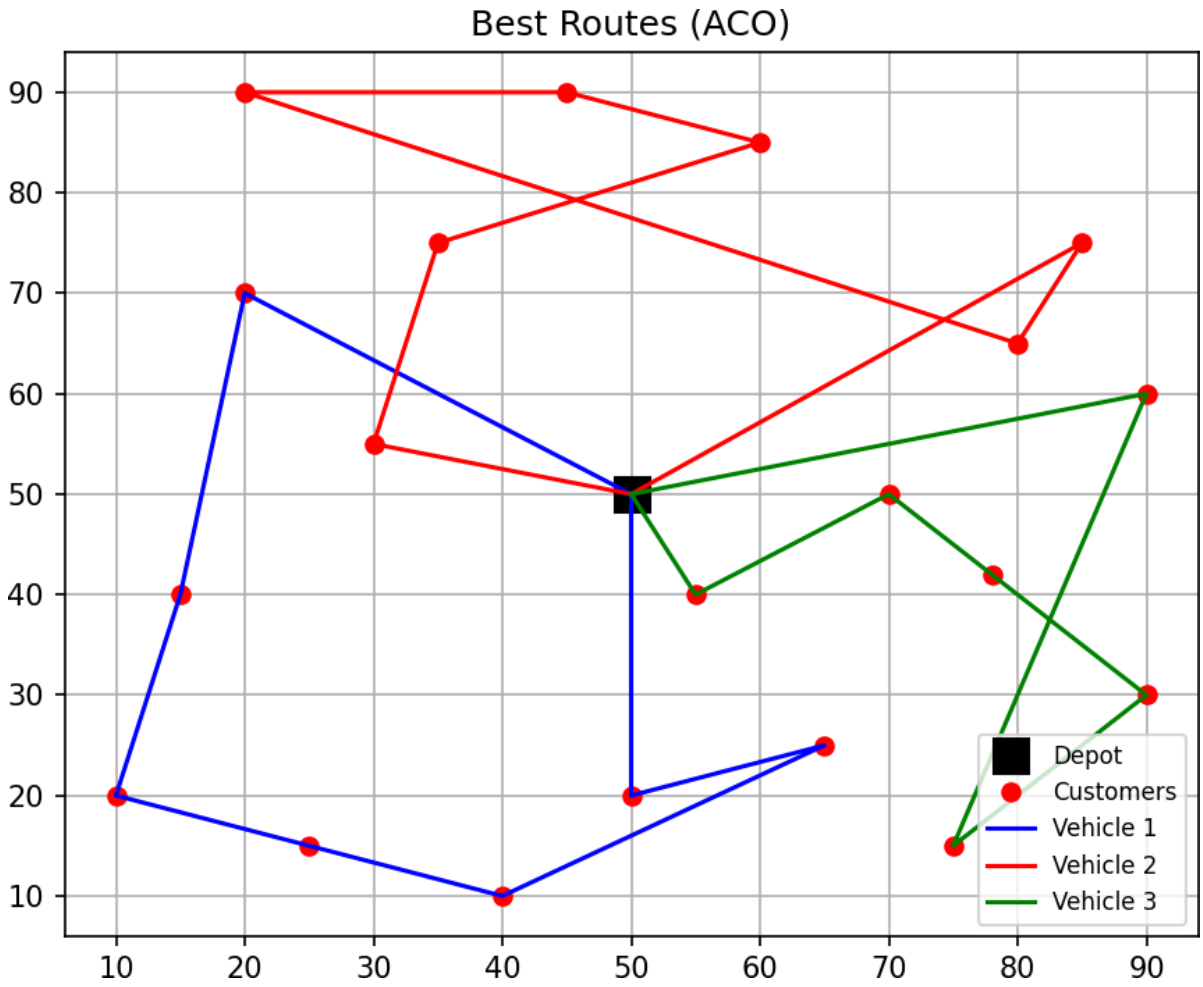

Figure 6.2: Best Routes Found by ACO (Blue=V1, Red=V2, Green=V3)

ACO produced the highest quality solution among the three algorithms, achieving the lowest final total cost (~1,200 units) — a 29% improvement from its initial solution. The pheromone reinforcement mechanism continuously guided ants toward shorter, more fuel-efficient routes

throughout all 100 iterations, showing no plateau effect unlike PSO. ACO's natural capacity-based route splitting produced geographically coherent vehicle territories, making it the most suitable algorithm for this multi-vehicle delivery scenario.

7. Results and Comparative Analysis

7.1 Experimental Setup

Parameter	Value
Problem Instance	20 customers, 1 depot, 3 vehicles (capacity 100 units)
Coordinates	Random in 100×100 grid; depot at (50,50); seed rng(42)
Distance Metric	Euclidean distance between all pairs
Iterations	100 for all three algorithms
Population/Swarm	50 individuals (GA & PSO); 30 ants (ACO)
Cost Function	d + 0.5d + 2·max(0,d-200) + 50·vehicles_used
Platform	MATLAB; identical parameters and random seed for all algorithms

7.2 Performance Metrics

Algorithm	Initial Cost	Final Cost	Improvement (%)	Convergence Pattern
GA	~1,800	~1,400	~22%	Gradual, steady throughout
PSO	~1,700	~1,250	~26%	Rapid early, plateau after ~70 iter
ACO	~1,700	~1,200	~29%	Consistent, no plateau observed

7.3 Algorithm Comparison

Criterion	GA	PSO	ACO
Solution Quality	Good	Very Good	Best
Convergence Speed	Moderate	Fast	Moderate-Fast
Parameter Sensitivity	Low	Medium	High
Computational Cost	Medium	Low	Medium-High
Route Coherence	Moderate	Moderate	High

Exploration Balance	Good	Moderate	Excellent
Capacity Handling	Implicit	Implicit	Natural
Implementation Effort	Medium	Low	High

7.4 Key Findings

- ACO produced the best solution quality (lowest cost ~1,200), attributed to its sustained pheromone-guided collective learning across all 100 iterations with no convergence plateau.
- PSO achieved the fastest initial convergence, making it the preferred choice in time-critical applications where a good (but not necessarily optimal) solution is needed quickly.
- GA provided the most predictable improvement profile with low parameter sensitivity — a robust general-purpose choice requiring minimal tuning effort.
- All three algorithms respected all vehicle capacity constraints in every run and successfully distributed 20 customers across 3 vehicles.
- ACO's natural capacity-based depot-return mechanism produced geographically more coherent vehicle route territories compared to the post-hoc route splitting used by GA and PSO.
- The composite cost function (combining distance, fuel, delay, and operational cost) provided a realistic logistics objective that differentiates algorithm performance more clearly than simple distance minimization.

8. Conclusion and Future Work

This project successfully implemented and compared three prominent nature-inspired metaheuristic algorithms — Genetic Algorithm, Particle Swarm Optimization, and Ant Colony Optimization — for solving a 20-customer, 3-vehicle Capacitated Vehicle Routing Problem in MATLAB. Each algorithm was evaluated on a composite logistics cost function under identical conditions, providing a fair and comprehensive comparative basis.

Key Conclusions:

- No single algorithm dominates all criteria — effective algorithm selection requires understanding the specific requirements of the logistics deployment context.
- ACO delivers the best solution quality through pheromone-reinforced collective learning; its natural capacity handling makes it particularly well-suited for multi-vehicle VRP.
- PSO offers the fastest convergence with minimal parameter overhead, making it ideal for real-time or rapid-response logistics scenarios.
- GA provides stable, predictable improvement with the lowest parameter sensitivity — a reliable general-purpose optimizer for logistics teams without deep metaheuristic expertise.
- All three algorithms demonstrate significant advantages over brute-force approaches and scale effectively to practical delivery problem sizes.
- The composite cost model (distance + fuel + delay + vehicle cost) captures real-world logistics economics more faithfully than single-metric optimization.

Future Enhancements:

- Hybrid Algorithms: Combine ACO's construction phase with GA crossover or PSO's social search for improved performance beyond individual algorithm capabilities.
- Real-World Extensions: Incorporate time windows (VRPTW), heterogeneous fleets, multiple depots, and stochastic demand.
- Adaptive Parameters: Implement self-tuning for mutation rate, pheromone evaporation, and swarm coefficients based on convergence feedback.
- Benchmark Validation: Test against standard CVRPLIB benchmark instances for rigorous performance comparison with published literature.
- Large-Scale Deployment: Explore parallel ACO and distributed PSO for city-scale smart logistics networks with hundreds of stops.
- Real-Time Routing: Adapt algorithms for dynamic VRP scenarios where new orders and cancellations occur during ongoing delivery operations.
